* *Journal was included in both psychology and I/O datasets*

** *Subsequently renamed Journal of Psychopathology and Clinical Science*

Table 2S. List of journals included in the I/O dataset (metaBUS: 1980-2017)

Journal name
Australasian Journal of Organisational Psychology
Academy of Management Journal
British Journal of Management
Employee Responsibilities and Rights Journal
European Journal of Work and Organizational Psychology
Group & Organization Management
Human Performance
Human Relations
Human Resource Management
Human Resource Management Journal
International Journal of Human Resource Management
International Journal of Selection and Assessment
Journal of Applied Psychology*
Journal of Applied Social Psychology
Journal of Business and Psychology
Journal of Management
Journal of Managerial Psychology
Journal of Organizational Behavior
Journal of Occupational Health Psychology*
Journal of Occupational and Organizational Psychology
Journal of Personnel Psychology
Journal of Vocational Behavior
The Leadership Quarterly
Organizational Behavior and Human Decision Processes
Personality and Individual Differences
Personnel Psychology
Work & Stress
<i>* Journal was included in both psychology and I/O datasets</i>

Note 1S. Exploratory Beta regression fit to the psychology dataset

An exploratory Beta regression was fit to the observed distribution of binned α values, with binned α s as the dependent variable and intercepts for the location (μ) and precision (ϕ) parameters. Model fit parameters were $\mu = 1.545$, $SE = 0.004$, $p < .0001$ and $\phi = 2.541$, $SE = 0.008$, $p < .0001$. Inspection of the model fit (see Table 1S) indicated worse fit than kernel smoothing with much unmodelled variance.

Figure 1S. Observed counts of α values with fitted Beta regression (upper panel) and residuals (lower panel) in the psychology dataset

Note 2S. Analyses of the I/O dataset after removing DOIs already present in the psychology dataset

The test of the first hypothesis found a 14% excess of α values of .70, $Z = 4.84$, $p < .00001$. The test of the second hypothesis found excesses across the three bins, $Z = 4.68$, $p = .00007$, with an excess at .80 = 3%, excess at .90 = 1%. We therefore rejected the null hypothesis that there was no evidence of no excesses of α values at common rule-of-thumb thresholds.

Figure 2S. Observed counts of α values with kernel smoothing (upper panel) and residuals (lower panel) in the I/O dataset, when overlap with the psychology dataset was removed

Figure 3S. Frequency of use of constructs in the I/O dataset

Note 3S. Caliper tests

We judged caliper tests to be less suitable for our current purposes than the kernel smoothing method on the basis that there are plausible distributional differences between adjacent bins (i.e., the distribution of α values is non-uniform, see Figures 1 and 2). For example, assuming the general distribution of α values observed in Figure 1 is roughly approximate to their true distribution, there are likely to be more observations of $\alpha = .78$ than $.77$ even in the absence of any distortions. Nonetheless, given the conceptual analogy between excesses of barely-significant p values and barely reliable α values, it is useful to include caliper tests as a robustness test given that they were employed in studies examining the distribution of p values (Hartgerink et al., 2016; Masicampo & Lalande, 2012). Caliper tests were not preregistered and were therefore exploratory. We employed a caliper width of one bin (i.e., $\alpha = .01$) and therefore compare counts between each bin and the preceding bin (i.e., $.69$ vs. $.70$, $.79$ vs. $.80$, and $.89$ vs. $.90$). Caliper ratios were calculated for each comparison in each dataset (i.e., counts of $.70$ divided by counts of $.69$). See Figure 2S for a visual illustration of how the kernel smoothing and caliper tests differ.

In the psychology dataset, the caliper ratio for the $\alpha = .70$ threshold 1.71. That is, roughly 70% more α values of $.70$ were observed than $.69$. This larger over abundance relative to the kernel density approach can be attributed to the fact that the caliper tests also take the under-abundance of α values in the pre-threshold bins (e.g., $.69$) as well as the over-abundance of values in the threshold bins (e.g., $.70$). Ratios for the other two thresholds were less extreme ($\alpha = .80$: ratio = 1.16; $\alpha = .90$: ratio = 1.02). See Figure 3S. Rather than compare these ratios against a null hypothesis of zero (due to the above distributional considerations), we instead then calculated a ratio for every bin and its preceding bin between $\alpha = .50$ and $.99$. In order to test whether the caliper ratios at the thresholds were larger than other ratios, we then applied permutation tests to compare the threshold ratios against all non-threshold ratios.

Results demonstrated that the $\alpha = .70$ caliper ratio was larger than the other ratios, $Z = 2.96$, $p = .02000$; and that the .70, .80, and .90 ratios were larger than the other ratios, $Z = 1.97$, $p = .02617$.

This pattern of results also generalized to the I/O dataset for two of the thresholds ($\alpha = .70$: ratio 1.64; $\alpha = .80$: ratio = 1.13; $\alpha = .90$: ratio = 0.96). See Figure 4S. The $\alpha = .70$ caliper ratio was again found to be larger than the other ratios, $Z = 2.34$, $p = .04$; however the .70, .80, and .90 ratios were not found to be larger than the other ratios, $Z = 1.40$, $p = .092$. The pattern of excesses at $\alpha = .70$ were therefore robust to the choice of analytic method. The collective excesses at all three thresholds were not robust in the I/O dataset. This may be because of large ratios observed at other round values of α which may have also been used as thresholds, but which we did not attempt to analyze (i.e., at .50 and .60; see Figure 4S).

Table 3S. Standard errors associated with Cronbach's $\alpha = .70$ for different sample sizes and numbers of items.

Sample size (n)	Number of items (k)					
	3	5	10	25	50	100
50	0.076	0.069	0.064	0.062	0.061	0.061
100	0.053	0.048	0.045	0.043	0.043	0.043
250	0.033	0.030	0.028	0.027	0.027	0.027
500	0.023	0.021	0.020	0.019	0.019	0.019
1000	0.016	0.015	0.014	0.014	0.014	0.013
2000	0.012	0.011	0.010	0.010	0.010	0.010
5000	0.007	0.007	0.006	0.006	0.006	0.006

Note 4S. The standard error associated with Cronbach's $\alpha = .70$ across a range of sample sizes (n) and numbers of items (k)

Cronbach's α 's variance is a function of (a) the value of α , (b) the sample size (n), and (c) the number of items or parcels (k) from which it was calculated (van Zyl et al., 2000). In order to assess whether α is sufficiently precisely estimated in common study designs that researchers could plausibly discriminate between scales whose population α values were .69 versus .70, we calculated the standard error of $\alpha = .70$ for a range of sample sizes and numbers of items. As can be seen in the table, standard errors ≥ 0.006 even when the number of participants and items are both very large (i.e., $n = 5000$, $k = 100$). Differences in population reliabilities of just $\alpha = .01$ would not be detectable in typical study designs, and therefore researchers could not genuinely calibrate their decisions on differences this small.
